15 **Abstract**

16 The fine-scale ecological determinants for wood-inhabiting aphyllorphoroid basidiomycetes
17 were investigated with statistical analyses of the occurrence of fruit bodies on woody debris
18 collected in Switzerland and Ukraine. Three substrate descriptors were considered: diameter,
19 degree of decomposition and host tree species.

20 By means of Multiple Regression Trees, thresholds in the response of fungal communities to
21 these local environmental descriptors were detected. Three classes for diameter, as well as for
22 degree of decomposition were thus delimited. They revealed the importance of very small sizes,
23 which were not reported in the literature so far: the relevant diameter class limits were about
24 0.72 cm and 1.35 cm. Within the host tree species, a clear distinction between coniferous and
25 broadleaf species was found. The next splits followed rather climatic determinants of tree
26 distribution than taxonomical entities such as families or genera.

27 The fidelity of the 59 fungal species to diameter classes, decomposition classes and host tree
28 species was measured by the Dufrêne-Legendre index and only significant responses after
29 permutation tests were retained. This brought new insights on the ecology of many wood-
30 inhabiting aphyllorphoroid basidiomycetes.

31 Redundancy Analysis was applied to investigate the response of fungal species to diameter and
32 degree of decomposition of woody debris from the most common host tree species, *Fagus*

1 *sylvatica*. This direct gradient analysis made it possible to reconstruct the succession of fungal
2 species along the wood decomposition process.

7 **Introduction**

8 Fungi play important roles in the forest ecosystems. They are the principal
9 decomposers of dead organic matter, such as dead wood and litter. Secondly, most of the tree
10 species depend on mycorrhizal symbiosis with fungal species (Smith and Read, 1997).

11 For the saprotrophic fungi, dead wood is one of the most important substrates in European
12 forests. Actually, dead wood may be called a key factor for biodiversity and functioning of the
13 temperate and boreal forests in Europe, as it provides substrate and shelter for many different
14 organisms, such as insects, birds, small mammals or fungi (e.g. Harmon et al., 1986; Primack,
15 2002). Among the wood-decomposing fungi, the aphyllorphoroid species are a major group,
16 regarding the importance for forest ecosystem functioning (Swift, 1982) as well as species
17 richness (Ryvarden and Gilbertsen, 1993, 1994; Hjortstam, 1997; Ginns, 1998).

18 In this study, we focus on two groups of aphyllorphoroid wood-inhabiting fungi: the
19 corticioid and poroid basidiomycetes. Among them, two ecological groups of fungi are
20 traditionally distinguished: saprotrophic and mycorrhizal species.

21 Corticioid and poroid fungal species are among the most important wood decomposing
22 fungi (Swift, 1982). As a general rule, the majority of the corticioid species perform white rot
23 wood decomposition, i.e. they decompose both the lignin and holocellulose wood components,
24 whereas the poroid species rather prefer the brown rot decomposition type, as they decompose
25 only the holocellulose wood components (Boddy and Rayner, 1988; Dix and Webster, 1995).

26 The corticioid mycorrhizal species discussed here belong to the ectomycorrhizal
27 forming species (Erland and Taylor, 1999). Several of these mycorrhizal species use dead wood
28 primarily as support to develop their fruit bodies. Whether they decompose wood in an
29 ecologically significant way is uncertain (Bruns, pers. comm.; Taylor, pers. comm.). However,
30 their mycorrhizal activities are broadly recognised and are vital for tree growth and
31 establishment (Smith and Read, 1997). Particularly in conifer forests, corticioid mycorrhizal
32 species are widespread and abundant. However, emphasis was only recently placed on these
33 hitherto often ignored resupinate species (Erland and Taylor, 1999; Kõljalg et al., 2000; Peter et
34 al., 2001).

1 The ecological requirements of the saprotrophic fungal species on their substrate were
2 investigated in various studies, especially in Northern Europe (e.g. Renvall, 1995; Høiland and
3 Bendiksen, 1996; Nordén et al., 2004) and some in Central Europe (Grosse-Brauckmann, 1999;
4 Dämon, 2001; Küffer and Senn-Irlet, 2005a). Three main characteristics of the dead wood
5 substrate were shown to be determinant: degree of decomposition of the wood, volume of the
6 dead wood fraction and host tree species (Heilmann-Clausen and Christensen, 2004; Heilmann-
7 Clausen et al., 2005; Küffer and Senn-Irlet, 2005b). Furthermore, these studies demonstrated
8 that the highest number of aphyllorphoroid fungal species is present when a high diversity of
9 substrate characteristics is provided. Thus, a great variability of dead wood, such as twigs,
10 branches or logs of different degrees of decomposition, volume and tree species, offers a wide
11 range of niches for wood-inhabiting fungi. Moreover, wood undergoes several physical and
12 chemical changes during the decay process (Leibundgut, 1982). Logs especially harbour a high
13 species richness as they do not decompose equally over the whole length and thus offer niches
14 for early and late stage species at the same time (Heilmann-Clausen and Christensen, 2003).

15 As representative sampling of dead wood is difficult, because of the extremely
16 heterogeneous spatial and temporal distribution (Bütler and Schlaepfer, 2004), the problem of
17 the appropriate size of dead woody debris to be sampled is not solved: for instance, Harmon et
18 al. (1986) only deal with dead woody debris with a minimum diameter of 10 cm. In the present
19 study, every debris of dead wood has been collected in the plots, in order to optimise the
20 delimitation of the diameter classes that influence fungal communities, using statistical
21 analyses.

22 The same principle has been applied to the degree of decomposition, whereas in
23 previous ecological studies, the degree of decomposition has only been measured with semi-
24 quantitative methods (e.g. Renvall, 1995). A determination of decomposition classes will be
25 attempted by statistical analysis, based on the collected data.

26 Host tree species is widely recognised as an important determinant factor in fungal
27 ecology, even more pronounced in agaricoid mycorrhizal species. The analyses presented in
28 this study add a new and more objective way of exploring the ecology of wood-inhabiting fungi
29 by applying different statistical methods.

30
31 Our study aims to test the following hypotheses: (1) The three ecological determinants
32 diameter, degree of decomposition and host species typically characterize species of wood-
33 inhabiting aphyllorphoroid basidiomycetes, (2) A distinct successional pathway among the
34 wood-decaying species exists and (3) Multivariate statistical methods, result in a different
35 substrate classification than proposed in the literature.

36

Material and Methods

The fungal samples were collected in a total of 104 rectangular plots of 50 m² in Switzerland and the Ukrainian Carpathian Mountains: 93 in Switzerland and 11 in the Ukrainian Carpathian Mountains. Forests in the five principal biogeographical regions of Switzerland (Gonseth et al., 2001) were chosen, in order to obtain an overview on the most frequent forests types in Switzerland and the main silvicultural management practices (Küffer and Senn-Irlet, 2005a). Within these forests the plots have been selected randomly.

The plots in Ukraine have mainly been chosen to include beech forests unaffected by human interventions (Brändli and Dowhanytsch, 2003). These sites are similar to the beech forests in Switzerland, with respect to temperature, precipitation, altitude, soil properties and tree growth capacity (Küffer and Senn-Irlet, 2004, Commarmot et al. 2005).

All dead woody debris in which at least one fruit body was observed were characterised according to the following descriptors: diameter, degree of decomposition and wood type (host tree species). The degree of decomposition was measured with a penetrometer PNR10 (PetrotestTM) according to Job (2002). To enable statistical analyses with the woody debris collected, the different types of wood were multiplied with their relative densities. The values for these calculations were drawn from Kučera and Gfeller (1994) and Sell (1997). A list of all fertile fungal species observed on every woody debris was used to build the binary community dataset.

In the 104 plots, 3518 woody debris with a total of 261 species of wood-inhabiting aphyllorphoroid basidiomycetes were collected. For more detailed information about data collection, determination and for a comprehensive species list, see Küffer et al. (2004) and Küffer and Senn-Irlet (2005b).

Three Multivariate Regression Trees (MRTs) were computed to determine thresholds in (1) degree of decomposition, (2) diameter and (3) host tree species, based on the overall response of the species assemblages (De'ath, 2002, 2006). Woody debris from rare host tree species (for which less than 10 debris by tree species were collected within the 104 plots) were not considered. Seven taxa were removed from the species dataset, because they were infertile and hence undeterminable. Therefore, the multivariate response was a community dataset with 2870 occurrences of 230 fertile fungal species.

Species preferences for the different decomposition, diameter classes or host tree species were calculated using the indicator value of Dufrêne and Legendre (1997). The indicator value IndVal was calculated for every species from its relative abundance and fidelity to each decomposition or diameter class or each host tree species.

General Additive Models (GAMs), constructed using penalised regression splines with a binomial response (Wood and Augustin, 2002; Wood, 2006), were fitted to the data for the most faithful species to diameter and decomposition classes.

Redundancy Analysis (RDA) was performed to provide an overall view of the determinism of fungal species assemblages (Legendre and Legendre, 1998; Oksanen et al., 2007). Only woody debris from the most common host tree species, *Fagus sylvatica*, were included. Rare fungal species with less than ten occurrences were removed from the community dataset. Hellinger transformation was applied to the species data prior to the constrained ordination, in order to avoid considering double absence of a species as a resemblance between objects (Legendre and Gallagher, 2001).

All statistical analyses were computed using R 2.4.1 (R Development Core Team, 2006).

Results

Constrained partitioning with Multivariate Regression Trees

The MRT constrained by the degree of decomposition divided the species dataset into three classes, according to two thresholds: the first one at 1.65 mm and the second one at 7.83 mm (Fig. 1).

For the diameter of woody debris, the MRT showed two main thresholds: a first one at 1.35 cm and a second one at 0.72 cm (Fig. 2). A third split at 2.15 cm was detected but, contrary to the two previous thresholds, it did not appear when considering either the full dataset (including missing values and all tree species) or the reduced dataset (without rare fungal species). Therefore, only the two first thresholds were retained for class delimitation and further fidelity analysis.

The third MRT with host tree species divided primarily the data according to a clear distinction between broadleaf (to the left) and coniferous (to the right) trees (Fig. 3). Among the broadleaf species, sweet chestnut (*Castanea sativa*) and oak (*Quercus* sp.) were grouped together in a separate branch. The four remaining broadleaf species, beech (*Fagus sylvatica*), black alder (*Alnus glutinosa*), birch (*Betula pendula*) and ash (*Fraxinus excelsior*) were located in the other branch. The further split isolated woody debris from *Fagus*. The coniferous species were arranged in four branches: in a first split fir (*Abies alba*) was separated from the other host trees. In a second step, European larch (*Larix decidua*) and stone pine (*Pinus cembra*) were

grouped into a single branch, opposed to Norway spruce (*Picea abies*) and Scots pine (*Pinus sylvestris*).

Fidelity analysis

Out of the 59 species with more than ten occurrences taken into account for the statistical analyses, 22 showed a significant preference for one of the decomposition class (Table 1). In the first decomposition class, i.e. very low degree of decomposition, seven species were found, among them the mycorrhizal species *Amphinema byssoides*, but also species growing in the first stages of the wood decomposition process, e.g. *Exidiopsis calcea*. The intermediate decomposition class was significantly preferred by four species, all of them saprophytic ones, such as *Hyphodontia sambuci*. The third class was characterized by a group of 11 species growing on strongly decayed wood. This group included several poroid species with more fleshy fruit bodies, such as *Skeletocutis nivea* or *Phellinus ferruginosus*, but also species adapted to the last stages in the decomposition process, such as *Schizopora paradoxa* or *Steccherinum fimbriatum* (Niemelä et al. 1995, Küffer & Senn-Irlet 2005b).

Only nine common species were significantly faithful to one of the diameter classes (Table 2). Among the species preferring very small branches and twigs, i.e. diameter class 1, two species of the genus *Athelia* were found. The species rather growing on coarse woody debris, i.e. diameter class 3, were *Botryobasidium subcoronatum* and *Scopuloides rimosa*.

Calculating fidelity values for host trees revealed that 20 fungal species showed a significant positive association with a single host tree species (Table 3). However, only nine out of the eleven host tree species were significantly associated to one or more fungal species. Beech and Norway spruce, the two most abundant tree species in this study, were not linked in a positive way to any fungal species. The highest number of significant fungal associations were with pines, oaks and birch.

The preferences of the most faithful species to one class of decomposition or diameter was verified by predicting the univariate response with a GAM (Fig. 4). For *Amphinema byssoides*, the fitted smooth response decreased linearly with the degree of decomposition. By contrast, *Hyphoderma praetermissum* showed a unimodal response with an optimum around 10 cm, whereas *Hyphodontia sambuci* showed a weak preference for low and intermediate degrees of decomposition.

Equally GAMs were calculated for the three diameter classes (Fig. 5). *Athelia epiphylla* represents the smallest diameter class up to 0.7162 cm. *Peniophora cinerea* is common on the intermediate diameter class. *Scopuloides rimosa* represents the thickest diameter class from 1.353 cm upward. In this GAM the preferences of this species for larger diameter is clearly emphasised.

1 **Redundancy Analysis**

2 Figure 6 shows a biplot of the Redundancy Analysis (RDA) with all the woody debris
3 of *Fagus sylvatica* and the most common fungal species. The two explanatory quantitative
4 variables, diameter and decomposition, were placed almost orthogonal, indicating that they
5 were not strongly correlated (Pearson's linear correlation: 0.139). They explained only 1.35%
6 of the variance of the Hellinger-transformed species matrix but they were significant
7 (permutation tests). However, the overall model and the two canonical axes were also
8 significant. The first axis was equally influenced by both variables.

9 The orthogonal projection of the species position on the decomposition axis allows
10 reconstructing the hypothetical succession along the decomposition process. On the upper right
11 of the plot, a series of species suggests the succession on fine branches and twigs, from
12 *Radulomyces confluens* and *Peniophora cinerea* to *Vuilleminia comedens* and *Trechispora* sp.
13 For moderate diameter, the succession starts from *Phanerochaete martelliana* and ends up with
14 *Schizopora paradoxa* or *Phellinus ferruginosus*. On the biggest branches, which are rarer, the
15 succession is less clear, but should involve *Hyphodontia crustosa* or *Botryobasidium vagum* in
16 the earliest stages, and *Hyphoderma praetermissum* or *Phlebiella vaga* in the latest stages of
17 decay. *Botryobasidium subcoronatum* is the most frequent species on big branches at various
18 degrees of decomposition.

21 **Discussion**

22 ***Diameter and decomposition classes***

23 The diameter and decomposition classes found by the regression tree analyses are
24 considerably smaller than indicated in the literature, often arbitrarily set: for the diameter
25 classes Kruys and Jonsson (1999) or Harmon et al. (1986) only deal with woody debris with a
26 diameter larger than 5 cm, as they defined the two woody debris categories: coarse woody
27 debris, CWD (≥ 10 cm diameter) and fine woody debris, FWD (5-9 cm diameter). Many studies
28 adopted these categories, but discussed the possibility of smaller categories (Nordén et al.,
29 2004; Eaton and Lawrence, 2006). So, Küffer and Senn-Irlet (2005a) introduced a new category
30 of woody debris, the very fine woody debris, VFWD (< 5 cm). However, in the present study,
31 the category limits are found to be even smaller. The importance of these very small branches
32 and twigs for fungal growth and fruiting were hitherto largely underestimated. They may have
33 been simply overlooked or not taken into consideration. They have a low potential as a nutrient
34 source for fungi and in addition an unfavourable surface-volume ratio, i.e. rather large surface,

1 but minor nutrient content. On the other hand, one might argue that these rather large surfaces
2 are more easily colonised by fungal species avoiding competition with other, more competitive
3 species, since these small twigs are only colonised by one single species at a time.

4 On the upper end of the scale, the branches, logs and trunks fall all into one single
5 category (> 1.353 cm diameter). So, the large woody debris categories do not seem
6 irreplaceable for the fungal community. Nevertheless, the importance of large logs and trunks
7 for the maintenance of a defined set of specialised species is largely recognised (Renvall, 1995;
8 Dämon, 2001; Heilmann-Clausen and Christensen, 2004).

9 The classes for the degree of decomposition are also rather low, i.e. skewed towards
10 the start of the decomposition process. This is also rather unexpected, as especially strongly
11 decomposed woody debris are assumed to harbour a wide diversity of fungal species (Lange,
12 1992; Niemelä et al., 1995; Lindblad, 1998; Heilmann-Clausen, 2001). However, our
13 observations fit into a general model of succession from generalists to specialists with
14 increasing competition. Quantified data from the literature on low decomposition stages is
15 scarce, because of the difficulty to measure the degree of decomposition in ecological studies.
16 Measuring degree of decomposition in the field is often done semi-quantitatively with a knife or
17 with the help of more or less subjective criteria (Renvall, 1995; Lindblad, 1998; Dämon 2001).
18 It is generally stated and accepted that a wide range of degrees of decomposition, viz. from
19 freshly fallen dead branches till completely decomposed wood, is needed, to offer suitable
20 habitat for many fungal species (Harmon et al., 1986; Küffer and Senn-Irlet, 2005b). This
21 finding is also underlined by the results of the beech RDA: the fungal species are distributed
22 over a wide range, when projecting them on the decomposition axis. The decomposition axis
23 may serve as a substitute for a temporal scale, which is nearly impossible to detect in a short
24 term study, such as the presented one.

25 ***Host tree species***

26 The regression tree analysis for the host tree species shows two main groups of hosts (Fig. 3):
27 coniferous and deciduous trees. These are the two main systematic groups of tree species. The
28 similarity within the fungal species inhabiting deciduous tree species is higher than within the
29 fungal species inhabiting conifer tree species. This pattern is also observed with the agaricoid
30 fungal species (Bieri et al., 1992), both in the saprophytic and the mycorrhizal species.
31 Generally, this analysis separates the coniferous trees more distinctively than the deciduous
32 ones. Fungal species growing on coniferous wood had more time to evolve independently, than
33 species growing on broadleaf wood, simply due to the older evolutionary age of coniferous
34 trees (Strasburger et al., 1991). Additionally, with the exception of *Abies alba* the different

1 deciduous trees occupy more often the same habitats than the coniferous species and form more
 2 frequently common vegetation units (Ellenberg and Klötzli, 1972).
 3 Within the coniferous host trees, four groups remain in the best regression tree, i.e. *Abies alba*,
 4 *Picea abies*, *Pinus sylvestris* and in one single group: *Larix decidua* and *Pinus cembra*. *Abies*
 5 *alba* is the most dissimilar of these four groups. This may be due to the rather moist habitats
 6 silver firs inhabit in Switzerland. In the Alps, *Abies alba* trees were admixed into broad-leaved
 7 deciduous forests since at latest the early to mid Holocene (i.e. 11500-6000 years ago), also into
 8 thermophilous forests, though human influence has partly shortened this co-habitation (Tinner
 9 et al., 1999; Gobet et al., 2000). The current wide-spread co-occurrence of *Abies alba* and
 10 *Fagus sylvatica* in Central Europe underscores the ecological affinity of silver with broadleaved
 11 deciduous trees (Ellenberg, 1996). In contrast *Picea abies*, *Pinus cembra* and *Larix decidua*
 12 reached higher altitudes, when broadleaf trees appeared (e.g. Tinner et al., 1999; Tinner and
 13 Ammann, 2005; Hofstetter et al., 2006). *Abies alba* is far less tolerant to cold temperatures and
 14 especially late frost events in spring time, than *Picea abies* (Schmidt-Vogt, 1977). However, fir
 15 may easier resist to drought and to windbreak events, due to the well developed root system
 16 (Schütt et al., 1984). The large distance to the *Larix decidua*/*Pinus cembra* group, may be
 17 interpreted ecologically: these two tree species grow in a special environment, the supra-
 18 subalpine zone (Steiger, 1994), where the influence of the climatic factors is very strong, and
 19 only host selective, co-evolved fungal species can succeed. On a first glance, it appears rather
 20 surprising to see *Picea abies* and *Pinus sylvestris* only separating with the last step. Ecological
 21 requirements between these two tree species seem rather different: Norway spruce more in the
 22 moist subalpine forest, *Pinus sylvestris* in the plain, on warm and dry habitats or on wetlands. A
 23 corresponding distance is also visible in evolutionary processes: *Picea abies* and *Pinus*
 24 *sylvestris* evolved rather independently (Price, 1995). However, in some areas of the Central
 25 Alps (e.g. Valais) these two species can form mixed coniferous forests in the upper mountain
 26 and lower subalpine belts, where samples were collected as well.
 27 Within the deciduous host trees, three groups remain in the best regression tree, i.e. *Castanea*
 28 *sativa* and *Quercus*; a group with *Fraxinus excelsior*, *Alnus glutinosa* and *Betula pendula*; and
 29 *Fagus sylvatica*. Abandoned *Castanea sativa* plantations predominantly occur in the Southern
 30 part of Switzerland, with an Insubrian climate, i.e. heavy rain falls, high annual precipitation
 31 amounts (reaching 2000 mm in the lowlands), combined with a relatively high temperature
 32 (annual average ca. 12° C) all the year around. *Quercus* rather prefers warmer and dry climate,
 33 nevertheless fungal associations seem to be similar. *Fagus sylvatica*, the most abundant
 34 deciduous tree species, often forming uniform stands, shows a remarkably diverse fungal
 35 community, different from the other deciduous tree species.

1 The other deciduous tree species, which remain together, all have somewhat similar ecological
2 requirements: *Fraxinus excelsior*, *Betula pendula* and *Alnus glutinosa* prefer rather wet
3 conditions, often growing in alluvial or riparian forests. These vegetation types are known to be
4 rather rich and with distinct fungal communities than other forest types (Bujakiewicz, 1989;
5 Lucchini et al., 1990; Griesser, 1992).

6 ***Fidelity analyses and GAMs***

7 The fidelity analyses showed some fungal species to have preferences for very small twigs or
8 large branches. Only 9 species are found to be significantly bound to one of the three diameter
9 class found with the regression tree analysis. There are probably still not enough data to detect
10 preferences of all species.

11 *Athelia epiphylla* is placed with very small twigs and branches (Table 1). This finding
12 is consistent with previous studies (Nordén and Paltto, 2001; Nordén et al., 2004; Küffer and
13 Senn-Irlet, 2005a). This preference is even found in forests where larger wood is present as
14 substrate, such as forests reserves or near-natural forests (Küffer and Senn-Irlet 2005b). Other
15 species prefer rather large woody debris such as logs and trunks. *Scopuloides rimosa* may serve
16 as an example for these species preferring coarse woody debris.

17 The degree of decomposition indicates where to place the species during the decomposition
18 process. It is assumed that by analysing spatially different stages of decay at a single moment,
19 certain conclusions on the succession in time can be drawn (e.g. Renvall, 1995). The early
20 decayers prefer dead wood freshly fallen from the trees, an example may be *Amphinema*
21 *byssoides*, a frequent and abundant species in conifer forests (Fig. 4). As the decomposition
22 process advances, the physical and chemical composition of the wood changes (Leibundgut,
23 1982; Boddy and Rayner, 1988) and with it also the fungal species composition (Renvall, 1995;
24 Niemelä et al., 1995). *Hyphodontia sambuci* may serve as an example for a fungal species
25 specialised to intermediate stages of decomposition while *Hyphoderma praetermissum* is
26 mostly found on later stages of the decomposition process.

27 Only few fungal species showed any significant host tree preferences (Table 3).
28 Among them we found associations already known, such as *Peniophora limitata* on *Fraxinus*
29 *excelsior* (Eriksson et al., 1978; Boidin, 1994) or *Coniophora arida* on *Pinus sylvestris*
30 (Hallenberg, 1985). On the other hand some species preferences could not be explained as
31 easily: *Stereum hirsutum* on *Castanea sativa* or *Vuilleminia comedens* on *Quercus*. Both
32 species have a broader host range according to the literature (Eriksson et al., 1978; Boidin et al.,
33 1994). However, the indicator value method assesses especially the relative abundance of a
34 fungal species within a host tree species, i.e. it takes into account how many woody debris of
35 each tree species has been found.

This fact may also in part explain why no fungal species was found to be associated with *Fagus sylvatica* or *Picea abies*, the two most abundant tree species.

Redundancy Analysis

A similar picture is visible in the RDA: the first axis represents the decomposition, the second axis the diameter. This order means also that the factor decomposition is stronger than the diameter for the characterisation of fungal substrate preferences. However, the presence of the small fraction of woody debris remains important for many fungal species (Heilmann-Clausen and Christensen, 2004; Nordén et al., 2004; Küffer and Senn-Irlet 2005b)

The same fungal species are highlighted in this analysis, as in the fidelity analyses. Especially for the decomposition process a succession path among the fungal species could be detected: from the pioneer species till late stage species.

Acknowledgements

We wish to thank Wolfgang Dämon (Salzburg) for kindly checking some critical specimens. We acknowledge Brigitte Commarmot (Birmensdorf), Vasyi Chumak (Uzhhorod), Pavlo Lovas (Uzhhorod) and Mychailo Mat'kovskyi (Uzhhorod) for help with organisation and field work. Willy Tinner (Zürich) is gratefully acknowledged for valuable comments on the manuscript and for help in collecting literature. We are grateful to the Swiss Federal Environmental Agency, Berne, and the Swiss National Science Foundation (programme SCOPES, Scientific co-operation with Eastern Europe) for funding.
